SYNTHETIC FATTY ACID DESATURASE GENE
FOR EXPRESSION IN PLANTS

This application claims priority to U.S. Provisional Application No. 60/097,586, filed August 24, 1998, the entirety of which is incorporated by reference herein.

5

FIELD OF THE INVENTION

This invention relates to the field of genetic engineering, and more particularly to transformation of plants with heterologous fatty acid desaturase genes
10   modified for optimum expression in plants.

BACKGROUND OF THE INVENTION

Several publications are referenced in this application in order to more fully describe the state of
15   the art to which this invention pertains. The disclosure of each of these publications is incorporated by reference herein.

Alteration of fatty acid desaturation in plants is of interest to plant biologists and food scientists
20   alike, due to the influence of unsaturated fatty acids on the health benefits and flavors of foods, as well as the role of these molecules in plant biological processes. For a nation interested in healthy diet, the quality of fats and oils depends on their fatty acid composition,
25   with oils high in monounsaturated fatty acids (e.g., canola, olive) gaining popularity as new health benefits are discovered. Considering the flavors of plant foods, many flavor-producing compounds are derived from peroxidation of unsaturated fatty acids. Thus, efforts
30   are being made to produce plants with increased amounts

-2-

of unsaturated fatty acids, preferably monounsaturated
fatty acids.

In animal and fungal cells, monounsaturated
fatty acids are aerobically synthesized from saturated

5   fatty acids by a microsomal Δ-9 fatty acid desaturase
that is membrane bound and cytochrome b_5-dependent. A
double bond is inserted between the 9- and 10-carbons of
palmitoyl (16:0) and stearoyl (18:0) CoA to form
palmitoleic (16:1) and oleic (18:1) acids. In the

10   reaction mechanism, electrons are transferred from NADH-
dependent cytochrome b_5 reductase, via the heme-containing
cytochrome b_5 (Cyt b_5) molecule, to the Δ-9 fatty acid
desaturase. The major form of cytochrome b_5 in animal,
fungal and plant cells exists as an independent protein

15   molecule that is anchored to the membrane by a short,
carboxyl terminal, hydrophobic stretch of amino acids.
The carboxyl terminal anchor orients the heme group of
the Cyt b_5 on the membrane surface and allows it to
translationally diffuse across the surface of the

20   membrane. This property of lateral mobility allows this
form of cytochrome b_5 to participate as an electron donor
to a number of different proteins that catalyze a variety
metabolic reactions on the membrane surface, including
fatty acid desaturases, various sterol biosynthetic

25   enzymes and a variety of cytochrome P450 mediated
reactions. While this contributes to the versatility of
Cyt b_5 as an electron donor, it also implies that the
major form of cytochrome b_5 shuttles between its redox
partners by translational diffusion across the surface of

30   the membrane (Strittmatter and Rogers, Proc. Natl. Acad.
Sci. USA, 72: 2658-2661, (1975; Lederer, Biochimie 76:
674-692, 1994). Furthermore, this mechanism suggests
that an independent, membrane bound cytochrome b_5 molecule

-3-

can potentially limit the rate of the metabolic reaction, depending on its abundance, its location on the membrane surface, its proximity to the electron acceptor, and the rate at which it can move and orient itself to the

5   acceptor on the membrane surface.

In plants, unsaturated fatty acids are formed and incorporated into complex lipids in two distinct cellular compartments. *De novo* fatty acid synthesis occurs almost exclusively in the plastids, producing the

10   saturated species 16:0-ACP (acyl carrier protein) and 18:0-ACP. 18:1-ACP is formed from 18:0-ACP in the plastid by a soluble, ferredoxin-dependent Δ-9 desaturase. These fatty acids are then shunted into one of two routes - a plastid-localized "procaryotic" pathway

15   or a cytosolic/ER (endoplasmic reticulum) "eucaryotic" pathway - for further modification and acylation into glycerolipids (Somerville and Browse, Science 252: 80-87, 1991). The acyl ACPs that are shunted into the prokaryotic pathway remain within the plastid and are

20   used for the synthesis of phosphatidic acid and further conversion to chloroplast glycerolipids. The fatty acyl groups of those lipids may be further desaturated by plastid desaturases that also use ferrodoxin as the electron donor.

25   Acyl-ACPs that are shunted into the eukaryotic pathway are converted to free fatty acids, transported across the chloroplast membrane into the cytoplasm where they are converted to acyl CoA thioesters by acyl CoA synthetase. Those fatty acids are then converted to

30   cytoplasmic/ER phosphatidic acid which can then be converted to membrane glycerophospholipids, or storage lipids, in the form of triacylglycerols and sterol esters that are the major components of plant oils.

-4-

Most polyunsaturated 18-carbon plant fatty acids appear to be formed in the cytosol by the ER-bound desaturases (Table 1). Once the 18:1 fatty acid is incorporated into phospholipid, an ER-bound desaturase can catalyze the formation of a Δ-12 double bond in the fatty acyl chain to form Δ-9,12 18:2. Other ER bound desaturase enzymes can act on 18:2 to introduce a Δ-15 double bond to form Δ9,12,15 18:3. These desaturase are thought to be similar to animal and fungal desaturases because they are membrane bound and appear to require a cytochrome b_5-mediated electron transport chain.

The conversion of saturated fatty acyl chains
to monounsaturated species in plants appears to be
confined to the chloroplasts. No Δ-9 desaturase activity
has been identified in the cytoplasm or endoplasmic
reticulum of plants. The soluble plant chloroplast Δ-9
desaturase is highly specific for 18:0-ACP as a substrate
and does not desaturate 16:0-ACP (Somerville and Browse,
supra). As a result, only a small amount of 16:1 is
present in most higher plants, while the pool of 16:0 is
concomitantly larger due to its disfavor as a substrate
for the plant desaturase. By comparison, a larger amount
of 18:1 is found in higher plant cells, with a
correspondingly lesser amount of 18:0. Thus, for the
purpose of increasing the concentration of mono-
unsaturated lipids in a plant, the 16:0 fatty acid
constitutes a significant pool of available substrate
that is under-utilized by the endogenous plant
desaturase.

In contrast to the plant Δ-9 desaturase, fungal
and animal Δ-9 desaturases efficiently convert a wide
range of saturated fatty acids with differing hydrocarbon
chain lengths to monounsaturated fatty acids. The
Saccharomyces cerevisiae enyzme, for example, efficiently
desaturates even and odd chain fatty acyl CoA substrates
from 13 carbons to 19 carbons in length. A broad
functional homology exists among various Cyt b_5-dependent
desaturases, as evidenced, for example, by the successful
expression of the rat Δ-9 desaturase in yeast (Stukey et
al., J. Biol. Chem. 265: 20144-20149, 1990).

-6-

The rat and yeast Δ-9 desaturase genes have been expressed in plants: both the rat and the yeast genes have been expressed in tobacco (Grayburn et al., BioTechnology 10: 675-678, 1992 (rat); Polashock et al.,
5 Plant Physiol. 100: 894-901, 1992 (yeast), and the yeast gene has also been expressed in tomato (Wang et al., J. Agric. Food Chem. 44: 3399-3402, 1996). The yeast Δ-9 desaturase has been shown to function in tobacco and tomato, leading to increases in the level of
10 monounsaturated fatty acids (both 16:1 and 18:1) and other compounds derived from monounsaturated fatty acids (e.g., polyunsaturated fatty acids, hexanal, 1-hexanol, heptanal, trans-2-octenal) (Polashock et al., supra; Wang et al; supra). Expression of the rat desaturase also led
15 to an increase in monounsaturated 16- and 18-carbon fatty acids (Grayburn et al., supra).

From the foregoing, it can be seen that transgenic plants expressing animal or fungal Δ-9 desaturase genes can be improved in their unsaturated
20 fatty acid composition by virtue of the activity of the foreign enzyme. Of further advantage, it has recently been discovered that some fungal Δ-9 desaturases (e.g., Saccharomyces cerevisiae) are fusion proteins comprising an intrinsic Cyt b_5 domain (Mitchell & Martin, J. Biol.
25 Chem. 270: 29766-29772, 1995). When this gene is expressed, sufficient Cyt b_5 is produced to drive the desaturase reaction at an optimum level and is not dependent on existing plant Cyt b_5. The known animal Δ-9 desaturases do not contain this fused Cyt b_5 motif and
30 must rely on independently-produced Cyt b_5 to provide the electrons for the reactions.

Though fungal or animal Δ-9 desaturases (e.g. the S. cerevisiae desaturase or the animal desaturases)

-7-

may be expressed and functional in certain plants, their
expression is likely less than optimal in plants, and
expression may not even be possible in other plant
species, due to several factors, including differences in
5   codon usage and codon preference in plants as compared to
fungi, and among different plant species and the presence
of cryptic intron splicing signals, among others. All of
these factors can lead to poor expression, or no
expression, of a non-plant foreign gene in a plant cell.

10   Accordingly, in order to make use of non-plant
fatty acid desaturases, particularly those such as the *S.
cerevisiae* Δ-9 desaturase comprising an internal Cyt b$_5$
motif, a need exists to design modified desaturase-
encoding DNA molecules that are customized for expression

15   in plant cells and specific plant tissues. It would be
of even greater advantage to optimize such modified DNA
molecules for expression in particular plant species,
such as those that are grown and harvested primarily for
oils.

20

SUMMARY OF THE INVENTION

                According to one aspect of the invention, a
synthetic fatty acid desaturase gene for expression in a
multi-cellular plant is provided, the gene comprising a

25   desaturase domain and a Cyt b$_5$ domain, wherein the gene is
customized for expression in a plant cytoplasm. In one
embodiment, the synthetic gene is customized for
expression in a monocotyledonous plant. In another
embodiment, the synthetic gene is customized for

30   expression in a dicotyledonous plant. In a preferred
embodiment, the synthetic gene is customized for
expression in a plant genus selected from the group
consisting of *Arabidopsis, Brassica, Phaeseolus, Oryza,*

-8-

Olea, *Elaeis* (Oil Palm) and *Zea*.

In a preferred embodiment of the invention, the desaturase is a cytosolic Δ-9 desaturase. The *Saccharomyces cerevisiae* Δ-9 desaturase is particularly

5   preferred.

In another embodiment of the invention, the synthetic gene is customized from a naturally occurring gene comprising both a desaturase domain and a cyt b_5 domain. Alternatively, the synthetic gene is a chimeric

10   gene comprising a desaturase domain and a heterologous cyt b_5 domain.

In another embodiment, the synthetic gene is customized from a naturally occurring gene such that the synthetic gene and the naturally occurring gene encode an

15   identical amino acid sequence. Alternatively, the synthetic gene is customized from a naturally occurring gene such that the synthetic gene and the naturally occurring gene encode a similar and functionally conserved amino acid sequence.

20   In another embodiment, a naturally occurring or a synthetic gene is customized so that specific amino acid modification are made to enhance the function of the encoded protein. Examples of such modifications include changing amino acids that are subjected to

25   phosphorylation or other post-translational modifications that may alter or regulate the activity of the Δ-9 desaturase enzyme.

In another embodiment of the invention, elements of a naturally occurring or a synthetic

30   desaturase gene that are not essential for enzymatic function are replaced or linked with elements derived from plant ER lipid biosynthetic genes that are normally expressed in maturing seeds or other plant tissues. The

-9-

improved expression of the modified gene produced by the inclusion or substitution of plant DNA sequences in the synthetic gene will result from native plant signal or control elements in those sequences that affect

5   desaturase gene expression at one or more levels.

According to another aspect of the invention, a method is provided for constructing and customizing a bifunctional desaturase/cyt b_5 encoding gene for expression in the cytosol of a multicellular plant. The

10   method comprises (a) providing a DNA molecule comprising a desaturase-encoding moiety operably linked to a cyt b_5-encoding moiety, said DNA molecule producing the bifunctional polypeptide in a non-customized form; (b) back-translating the polypeptide sequence using preferred

15   codons for expression in a multicellular plant, thereby producing a back-translated nucleotide sequence; (c) analyzing the back-translated nucleotide sequence for features that could diminish or prevent expression in the plant cytoplasm, including, optionally (1) probable

20   intron splice sites (characterized by T-rich regions); (2) plant polyadenylation signals (e.g., AATAAA); (3) polymerase II termination sequence (e.g., $CAN_{(7-9)}AGTNNAA$, where N is any nucleotide); (4) hairpin consensus sequences (e.g., UCUUCGG); and (5) the sequence-

25   destabilizing motif ATTTA; (d) modifying the analyzed sequence to correct or remove the features that could diminish or prevent expression in the plant cytoplasm; and, optionally, (e) introducing desirable cloning features, such as restriction sites, into the sequence in

30   a manner that does not materially affect the desired codon usage or final polypeptide sequence.

The method set forth above may be adapted by incorporating into the customized gene one or more

-10-

genomic segments from plant desaturase or other ER lipid
biosynthetic genes, which are determined to further
optimize gene expression in plants. This method
comprises (1) identifying cDNA sequences that have
5   potential to comprise such beneficial elements, (2)
creating yeast vectors expressing desaturase genes
modified to contain these elements, (3) testing the
vectors in a yeast expression system, (4) isolating
regions from genomic DNA that are homologous to the
10   beneficial cDNA elements, and (6) using them to construct
chimeric or hybrid synthetic genes that produce
functional and highly efficient desaturase activities in
plant tissues.

15   Other features and advantages of the present
invention will be better understood by reference to the
drawings, detailed description and examples that follow.

BRIEF DESCRIPTION OF THE DRAWINGS

b_5 protein sequences.

DETAILED DESCRIPTION OF THE INVENTION
        I.   Definitions
30   Various terms relating to the biological
molecules of the present invention are used herein above
and also throughout the specifications and claims.
        The term "promoter region" refers to the 5'

-11-

regulatory regions of a gene.

The term "reporter gene" refers to genetic sequences which may be operably linked to a promoter region forming a transgene, such that expression of the reporter gene coding region is regulated by the promoter and expression of the transgene is readily assayed.

The term "selectable marker gene" refers to a gene product that when expressed confers a selectable phenotype, such as antibiotic resistance, on a transformed cell or plant.

The term "operably linked" means that the regulatory sequences necessary for expression of the coding sequence are placed in the DNA molecule in the appropriate positions relative to the coding sequence so as to effect expression of the coding sequence. This same definition is sometimes applied to the arrangement of coding sequences and transcription control elements (e.g. promoters, enhancers, and termination elements) in an expression vector.

The term "DNA construct" refers to genetic sequence used to transform plants and generate progeny transgenic plants. These constructs may be administered to plants in a viral or plasmid vector. Other methods of delivery such as Agrobacterium T-DNA mediated transformation and transformation using the biolistic process are also contemplated to be within the scope of the present invention. The transforming DNA may be prepared according to standard protocols such as those set forth in "Current Protocols in Molecular Biology", eds. Frederick M. Ausubel et al., John Wiley & Sons, 1999.

This invention provides synthetic DNA molecules (sometimes referred to herein as "synthetic genes") that

-12-

encode a fatty acid desaturase useful for modifying the fatty acid composition of a plant. The DNA molecules describe in accordance with this invention are superior to DNA molecules currently available for this purpose, in

5   two important respects: (1) they encode a dual-domain polypeptide (sometimes referred to herein as a "bifunctional polypeptide or protein"), one domain being the fatty acid desaturase, and the other domain being cytochrome b_5, a protein required to support the electron

10   transfer events that enable the desaturase to function; and (2) they are customized for expression in the cytosol of plant cells, and further customized for expression in particular selected plant species.

Design of synthetic genes of the present

15   invention is accomplished in two broad steps. First, the two components (the desaturase-encoding component and the Cyt b_5-encoding component) are selected and linked together, if they do not occur together naturally. Second, the DNA molecule is optimized for expression in

20   the cytosol of a plant cell, or further for expression in a particular plant species, or group of species.

With regard to the first step, it should be noted that several fungal, animal and plant species, including yeast, are now known to contain naturally-

25   occurring genes encoding dual-domain cytoplasmic fatty acid desaturases. As mentioned above, the yeast and rat Δ-9 desaturase genes have been expressed and shown to function in plants. However, prior to the present invention, it was not appreciated that the bifunctional

30   yeast desaturase offers a significant advantage over the single-function animal desaturase in plant cells, where the requisite Cyt b_5 is available only in small amounts, and the yeast protein can provide its own supply of Cyt

-13-

b_5.

        With regard to the second step - optimization
for expression in the plant cytosol - it was discovered
in accordance with the present invention that a non-plant
desaturase-encoding gene, such as the yeast *OLE 1*, though
expressed in some plants, may not be optimally expressed
in those plants. Furthermore, the inventors have found
that the yeast gene is poorly expressed in other plant
species, thus highlighting the advantages obtainable by
optimizing such a gene for expression in a plant cell.

        Sections II-IV below describe in detail how to
design and use the synthetic genes of the present
invention. To the extent that specific materials are
mentioned, it is merely for purposes of illustration and
is not intended to limit the invention. Unless otherwise
specified, general biochemical and molecular biological
procedures, such as those set forth in Sambrook et al.,
Molecular Cloning, Cold Spring Harbor Laboratory (1989)
(hereinafter "Sambrook et al.") or Ausubel et al. (eds)
Current Protocols in Molecular Biology, John Wiley & Sons
(1999) (hereinafter "Ausubel et al.") are used.

II. **Design and construction of the synthetic DNA molecules**
        A.   **Selection of component DNA segments**
        This invention contemplates the use of the
following source DNAs, which are thereafter modified for
expression in plants, if necessary:
        1.   naturally occurring genes or cDNAs that
encode dual domain polypeptides comprising a desaturase
domain and a Cyt b_5 domain;
        2.   chimeric genes in which a desaturase-
encoding sequence from one source (e.g., the desaturase
domain of a dual domain fungal Δ-9 desaturase, or the

-14-

single domain rat desaturase), is linked to a Cyt b_5-
encoding sequence from a different source (e.g., a
plant);

    3. chimeric genes in which a sequence that
encodes a fragment of a naturally occurring plant Cyt b_5
(e.g. the heme binding fold, or residues that comprise
the electron donor or acceptor sites, or residues that
act as membrane targeting or retention signals, or
residues that act to stabilize the protein in the plant
cytoplasmic environment) is substituted for homologous
regions in the cytochrome b_5 domain of a dual domain
polypeptide such as the yeast Δ-9 desaturase; and

    4. chimeric genes in which elements that encode
the essential enzymatic domains from one source (e.g. a
native or synthetic gene derived from a fungal Δ-9
desaturase) are linked to elements derived from native
plant desaturases that enhance transcription, mRNA
processing, mRNA stability, protein folding and
maturation, membrane targeting or retention, or protein
stability.

    Naturally occurring genes or cDNAs that encode
dual domain desaturase/Cyt b_5 proteins have been
identified in several fungal species, including
Saccharomyces cerevisiae, *Pichia augusta*, *Histoplasma
capsulatum* and *Cryptococcus curvatus* (See Fig. 1).
Naturally occurring genes or cDNA=s that encode
independent, diffusible Cyt b_5 proteins have been
identified in several plant species, including *Nicotiana
tabacum* (tobacco), *Oryza sativa* (rice), *Cuscuta reflexa*
(southern Asian dodder), *Arabidopsis thaliana*, *Brassica
oleracea* and *Olea europaea* (olive). A N-terminal Cyt b_5
domain of a Δ-6 desaturase has also been identified in
the plant *Borago officinalis*, and in the *Saccharomyces*

-15-

cerevisiae FAH1 gene that encodes a very long chain fatty acid hydroxylase. Genes or cDNAs from these species, as well as DNA from any other species identified in the future as encoding such a dual domain protein, are contemplated for use in the synthetic genes of the present invention.

In a preferred embodiment, the yeast *OLE1* gene is used. This embodiment is described in detail in Example 1.

The second strategy involves linking a DNA segment encoding a fatty acid desaturase from one source with a Cyt b_5 domain from another source. In a preferred embodiment, this chimeric gene is fashioned after the naturally-occurring dual function genes discussed above. That is, the Cyt b_5 domain and the desaturase domain are situated in the same positions respective to each other as is found in the naturally occurring genes (see, e.g., Mitchell & Martin, J. Biol. Chem. 270: 29766-29772, 1996).

The chimeric dual-domain proteins of the invention are prepared by recombinant DNA methods, in which DNA sequences encoding each domain are operably linked together such that upon expression, a fusion protein having the desaturase and Cyt b_5 functions described above is produced. As defined above, the term "operably linked" means that the DNA segments encoding the fusion protein are assembled with respect to each other, and with respect to an expression vector in which they are inserted, in such a manner that a functional fusion protein is effectively expressed. The selection of appropriate promoters and other 5' and 3' regulatory regions, as well as the assembly of DNA segments to form an open reading frame, employs standard methodology well

-16-

known to those skilled in the art.

Thus, preparing the chimeric DNAs of the invention involves selecting DNA sequences encoding each of the aforementioned components and operably linking the

5   respective sequences together in an appropriate vector. The sequences are thereafter expressed to produce the dual-function protein.

Genes or cDNAs that encode single-function cytoplasmic Δ-9 fatty acid desaturases have been

10   identified in a diverse array of procaryotic and eucaryotic species, including insects, fungi and mammals, but not plants (Fig. 1). Genes or cDNAs from any of these species, as well as DNA from any other species identified in the future as encoding a fatty acid

15   desaturase, are contemplated for use in the synthetic genes of the present invention.

In preferred embodiments, desaturase-encoding genes from eucaryotes, most preferably fungi or mammals, are used. In a particularly preferred embodiment, a DNA

20   encoding the rat stearoyl CoA desaturase is used. This DNA has been successfully expressed in tobacco, and accordingly is expected to be useful as part of a chimeric desaturase/Cyt b_5 gene of the present invention.

Genes or cDNAs that encode Cyt b_5 proteins have

25   also been identified in a diverse array of eucaryotic species, including insects, fungi, mammals and plants. Genes or cDNAs from any of these species, as well as DNA from any other species identified in the future as encoding a Cyt b_5 protein, are contemplated for use in the

30   synthetic genes of the present invention.

In preferred embodiments, Cyt b_5-encoding genes or cDNAs from plants are used. These DNAs are preferred because they naturally comprise the codon usage preferred

-17-

in plants, so require little, if any, of the modification
steps described below for non-plant genes. Particularly
preferred, if available, are Cyt b_5-encoding DNAs from the
same plant species (or group of species) to be

5   transformed with the chimeric gene. For instance,
synthetic chimeric genes constructed for transformation
of *Brassica* species might comprise a stearoyl CoA-
encoding domain from rat and a Cyt b_5 domain from *Brassica*
(see Figs. 1 and 2 for specific sources). This chimeric

10   DNA would require optimization for expression in *Brassica*
only in the desaturase domain.

With respect to the naturally-occurring dual
domain-encoding genes, as well as the chimeric genes
discussed above, it will be appreciated that the DNA

15   molecules can be prepared in a variety of ways, including
DNA synthesis, cloning, mutagenesis, amplification,
enzymatic digestion, and similar methods, all available
in the standard literature. Additionally, certain DNA
molecules can be obtained by access to public

20   repositories, such as the American Type Culture
Collection. Alternatively, DNA molecules that are not
readily available, and/or for which sequence information
is not available, can be isolated from biological sources
using standard hybridization methods and homologous

25   probes that are available.

B.   **Optimization for expression in plants**

The second step in designing the synthetic DNA
molecules of the invention is to customize (i.e.

30   optimize) their sequence for expression in the plant
cytoplasm. This is accomplished by performing one or
more of the steps listed below on the coding sequence of
the above described non-plant (or chimeric)

-18-

desaturase/Cyt b_5-encoding DNA molecules.

    1. From the peptide sequence encoded by the
DNA, back translate using an appropriate plant codon
usage table, making certain in particular that the most
5   preferred translation termination codon is used.

    2. Visually, or with the aid of computer
software, analyze the back-translated nucleotide sequence
for features that could diminish or prevent expression in
the plant cytoplasm. Such features include: (1) probable
10 intron splice sites (characterized by T-rich regions);
(2) plant polyadenylation signals (e.g., AATAAA); (3)
polymerase II termination sequence (e.g., $CAN_{(7-9)}AGTNNAA$,
where N is any nucleotide); (4) hairpin consensus
sequences (e.g., UCUUCGG); and (5) the sequence-
15 destabilizing motif ATTTA (Shah & Kamen, Cell $\underline{46}$: 659-
667, 1986). These features have been described in the
art (U.S. Patent No., 5,500,365 to Fischhoff et al.; U.S.
Patent No. 5,380,831 to Adang et al.).

    3. Modify the back-translated sequence in
20 light of any "problem" sequences identified in step 2.
Note that this step may require the introduction of
codons that are not the most preferred, but instead are
second or third-most preferred, in order to eliminate the
more problematic sequences identified in step 2.

25   4. Introduce desirable cloning features, such
as restriction sites, into the sequence in a manner that
does not materially affect the desired codon usage or
final polypeptide sequence.

    The aforementioned optimization procedure can
30 be performed so that the final polypeptide sequence is
identical to the initial polypeptide sequence, even
though the underlying nucleotide sequence has been
modified. This is a preferred embodiment of the

-19-

invention. However, it is entirely feasible to modify
the initial sequence such that the final sequence is not
identical to the initial sequence, either by virtue of
amino acid substitutions, insertions or deletions. The
5   more that is known about the structure/function
relationship in a particular desaturase protein, the more
liberties can be taken in modifying the protein sequence
during the DNA optimization process. For instance, the
present inventors have shown that the entire "coiled
10   coil" domain of the yeast *OLE1* gene can be deleted, and
the protein remains functional. Thus, it appears that
OLE1 can tolerate significant modification in the encoded
protein without losing its biological activity.

Codon usage tables for a variety of plants,
15   including general plant codon usage tables, tables for
dicots, tables for monocots, and tables for particular
species, are widely available. Some of these are
reproduced in Example 1 below. One good location to
access such tables is the website:

20

http://biochem.octago.ac.nz.800/Transterm/codons.html.

In an exemplary embodiment of the present
invention, the above process is applied to the coding
25   sequence of the yeast *OLE1* gene, which encodes a
cytoplasmically expressed dual-domain protein comprising
a Δ-9 fatty acid desaturase domain and a Cyt b_5 domain.
Optimization of the *OLE1* gene for expression in
Arabidopsis and related species is described in detail in
30   Example 1.

In another preferred embodiment, the coding
sequence of the rat stearoyl CoA desaturase is modified
for expression in plants according to the methods

-20-

described above. The modified sequence is operably
linked to a coding sequence for a Cyt b_5 domain,
preferably from a plant, and most preferably from
Brassica. In this regard, it has been shown that
5   expression of this rat desaturase in tobacco produces a
functional protein that increases the 16:1 fatty acid
content of plant tissues. Splice site prediction
analysis of the rat desaturase reveals that there are no
plant intron-like sequences within the open reading
10 frame. However, codon usage analysis reveals that this
desaturase possesses a number of codons that are not
optimal for expression in plants, particularly
Arabidopsis or *Brassica*.

In another preferred embodiment, the protein
15 coding sequences of the modified vectors described above
are further modified to increase desaturase activity.
This is done by altering specific amino acids in the
encoded protein that control desaturase activity through
post-translational modifications. These modifications
20 are presumed to increase the level of desaturase activity
in the host plant by stabilizing the desaturase protein
or by increasing catalytic activity of the desaturase.
Post translational modifications such as protein
phosphorylation or dephosphorylation have been shown to
25 alter activity of a number of enzymes by a number of
different mechanisms. These include increasing or
decreasing enzyme activity or protein stability, or
changing the intracellular location of the enzyme. An
examination of a wide range of Δ-9 desaturase enzymes
30 reveals the existence of a number of highly conserved
potential phosphorylations sites that could serve as
sequences that regulate desaturase activity. These are
shown in bold face on the pile-up diagram in Figure 3 and

-21-

are summarized in Table 1 of Example 3. The high degree
of homology between these sites suggests that these
sequences may also be recognized by host plant
phosphorylating or dephosphorylating enzymes. If

5   phosphorylation of an amino acid within one of the sites
increases the activity of the desaturase, the nucleic
acid sequence corresponding to that amino acid can be
altered to encode a negatively charged amino acid at that
site to permanently increase the activity of the protein

10 in the host. If phosphorylation of an amino acid within
the site reduces the activity of the desaturase enzyme,
the nucleic acid sequence can be altered to replace that
amino acid with a neutral amino acid that will
permanently increase the activity of the enzyme.

15   In another preferred embodiment, elements of
the genes in the modified vectors described above are
further modified and improved by the linkage or
substitution of sequences derived from native plant ER
lipid biosynthetic genes. Those sequences contain

20 elements that improve the desaturase activity by
increasing the efficiency of gene expression,
intracellular protein targeting and/or enzyme stability.
This is done by identifying elements of the engineered
desaturase gene that can be replaced or linked with

25 elements of a plant gene without significantly affecting
the desired activity or specificity of the resulting
enzyme. Genes and cDNAs that encode ER lipid
biosynthetic enzymes from *Brassica*, *Arabidopsis*,
Nicotiana tabacum, Borage, maize, sunflower and soybeans,

30 as well as similar plant genes from any other species
that are identified in the future, are contemplated for
use in the synthetic genes of the present invention.
        In connection with the aforementioned

-22-

embodiment, but not limited thereto, it is particularly
useful in many cases to pre-test constructs of the
invention in a yeast expression system, in order to
eliminate constructs that work poorly before taking the

5   more labor- and time-intensive step of testing them in
plants. Accordingly, this step may be incorporated into
the methods described herein.

10   **III.   Construction of vectors for transforming plant
             nuclei, and production of transgenic plants
             expressing synthetic genes of the invention**

             The synthetic genes of the present invention

15   are intended for use in producing transgenic plants that
optimally express a dual-function desaturase/Cyt b_5
protein in the cytoplasm of plant cells. Transformation
of plant nuclei to produce transgenic plants may be
accomplished according to standard methods known in the

20   art. These include, but are not limited to,
Agrobacterium vectors, PEG treatment of protoplasts,
biolistic DNA delivery, UV laser microbeam, gemini virus
vectors, calcium phosphate treatment of protoplasts,
electroporation of isolated protoplasts, agitation of

25   cell suspensions with microbeads coated with the
transforming DNA, direct DNA uptake, liposome-mediated
DNA uptake, and the like. Such methods have been
published in the art. See, e.g., Methods for Plant
Molecular Biology, Weissbach & Weissbach eds., Academic

30   Press, Inc. (1988); Methods in Plant Molecular Biology,
Schuler & Zielinski, eds., Academic Press, Inc. (1989);
Plant Molecular Biology Manual, Gelvin Schilperoort,
Verma, eds., Kluwer Academic Publishers, Dordrecht
(1993); and Methods in Plant Molecular Biology - A

35   Laboratory Manual, Maliga, Klessig, Cashmore, Gruissem &

-23-

Varner, eds., Cold Spring Harbor Press (1994).

The method of transformation depends upon the plant to be transformed. The biolistic DNA delivery method is useful for nuclear transformation, and is a preferred method for practice of this invention. In another embodiment of the invention, *Agrobacterium* vectors are used to advantage for efficient transformation of plant nuclei.

In a preferred embodiment, the synthetic gene is introduced into plant nuclei in *Agrobacterium* binary vectors. Such vectors include, but are not limited to, BIN19 (Bevan, Nucl. Acids Res., 12: 8711-8721, 1984) and derivatives thereof, the pBI vector series (Jefferson et al., EMBO J., 6: 3901-3907, 1987), and binary vectors pGA482 and pGA492 (An, Plant Physiol., 81: 86-91, 1986). A new series of *Agrobacterium* binary vectors, the pPZP family, is preferred for practice of the present invention. The use of this vector family for plant transformation is described by Svab et al. in Methods in Plant Molecular Biology - A Laboratory Manual, Maliga, Klessig, Cashmore, Gruissem and Varner, eds., Cold Spring Harbor Press (1994).

Using an *Agrobacterium* binary vector system for transformation, the synthetic gene of the invention is linked to a nuclear drug resistance marker, such as kanamycin or gentamycin resistance. *Agrobacterium*-mediated transformation of plant nuclei is accomplished according to the following procedure:

(1) the gene is inserted into the selected *Agrobacterium* binary vector;

(2) transformation is accomplished by co-cultivation of plant tissue (e.g., leaf discs) with a suspension of recombinant *Agrobacterium*, followed by

-24-

incubation (e.g., two days) on growth medium in the
absence of the drug used as the selective medium (see,
e.g., Horsch et al., Science 227: 1229-1231, 1985);

(3) plant tissue is then transferred onto the
selective medium to identify transformed tissue; and

(4) identified transformants are regenerated
to intact plants.

It should be recognized that the amount of
expression, as well as the tissue specificity of
expression of the synthetic genes in transformed plants
can vary depending on the position of their insertion
into the nuclear genome. Such position effects are well
known in the art; see Weising et al., Ann. Rev. Genet.,
22: 421-477 (1988). For this reason, several nuclear
transformants should be regenerated and tested for
expression of the synthetic gene.

**IV. Uses of the synthetic genes and transgenic
      plants expressing those genes**

The synthetic desaturase genes of the invention
and transgenic plants expressing those genes can be used
for several agriculturally beneficial purposes. For
instance, they can be used in oil-producing crops (e.g.,
corn, soybean, sunflower, rapeseed) to increase the
overall percentages of monounsaturated fatty acids in
those oils, thereby improving their health-promoting
qualities. In this regard, the production of transgenic
rapeseed plants (*Brassica napus*) is of particular
interest in this invention. Example 1 describes a
synthetic yeast desaturase gene modified for expression
in *Arabidopsis*. Because the codon usage of *Brassica* is
very similar to that of *Arabidopsis*, it is expected that
the synthetic gene described in Example 1 will be as well

-25-

expressed in *Brassica* as it is in *Arabidopsis*.

Another use for the synthetic genes of the invention is to modify the flavors of certain fruit or vegetable crops. It has already been shown that expression of the un-modified yeast Δ-9 desaturase gene in tomato results in alterations in fatty acid composition and fatty acid-derived flavor compounds (Wang et al., 1996, *supra*). The synthetic, plant-optimized version of this gene is expected to function similarly, and also to be more efficiently expressed in plant cells.

Another use for the synthetic genes of the invention is to facilitate the formation of omega-5 anacardic acids, a class of secondary compounds derived from the Δ-9 desaturation of 14:0 in pest-resistant geraniums (Schultz et al., Proc. Natl. Acad. Sci. USA, 93: 877-885, 1996). It has been shown that formation of these compounds proceeds from the expression of Δ9 desaturase activity resulting in the formation of Δ9 14:1. Subsequent elongation of these molecules leads to the formation of omega-5 22:1 and 24:1 in the trichome exudate that leads to pest resistance against spider mites and aphids.

Another use for the synthetic genes of the invention are in the modification of membrane lipid fatty acyl composition to alter the properties of the cytoplasmic and plasma membranes of the cell. These may affect functions such membrane associated activities that are associated with membrane functions such as signal transduction, endocytosis or exocytotic events, entry of fungal or viral pathogens into the cell, and temperature or environmentally caused stress that causes physical changes in the fluid properties of the plasma membrane or internal cell membranes. Plants defective in desaturases

-26-

have been reported (Somerville and Browse, *supra*). These
mutant plants contain higher than normal levels of
saturated fatty acids that may lower membrane fluidity
under normal growing conditions. Thus the effects of
temperature on these plants involved high temperature
tolerance as opposed to chilling tolerance. These
studies yielded interesting information that has
relevance to temperature stress in general. A mutant of
Arabidopsis deficient in 16:0 desaturation (Hugly *et al*,
Plant Physiol. 90: 1134-1142) for example, has been shown
to appear and grow normally at non-stressful
temperatures. Under high temperature conditions,
however, the mutant performs better than controls in
growth and biosynthetic studies. Higher temperature
stability was also noted in pea thylakoids following
catalytic hydrogenation (Thoman et al. Biochem. Biophys.
Acta <u>849</u>: 131-140, 1986).

        The following examples are provided to describe
the invention in greater detail. They are intended to
illustrate, not to limit, the invention.

EXAMPLE 1
Modification of the *Saccharomyces cerevisiae OLE1* Gene
for Expression in *Arabidopsis* and Related Species

        When introduced into tobacco and tomato plants,
the yeast Δ-9 desaturase gene (*OLE1*) was shown to
desaturate palmitate and stearate, thereby reducing the
levels of saturated fatty acids in triglycerides
(Polashock et al., *supra*; Wang et al., *supra*). However,
it was unclear whether optimum expression of the *OLE1*
gene occurred in those species, and expression in other

plant species has been less than optimum. For example,
the present inventors have found that the level of
expression of the OLE1 gene in tobacco (Polashock, et.
al., Plant Physiol. 100:894-901, 1992) and *Arabidopsis*
varies in different plant tissues and is generally poor
in tobacco, and Arabidopsis seeds. Similarly, data from
other investigators indicate that expression of OLE1 in
rapeseed (*Brassica napus*) seeds is also poor (U.S. Patent
No. 5,777,201, to Poutre, et al.).

Differential expression of heterologous genes
in plants can be caused by several factors. It is often
due to the presence of cryptic intron splicing signals.
Thus, it is possible that the multiple banding patterns
observed in northern blots of *OLE1*-transformed tobacco
(Polashock et al., *supra*) are due to splicing of the *OLE1*
mRNA.

In plants, the mRNA splicing mechanism is less
well defined than in mammalian or yeast systems. There
is some conservation of the 5' and 3' splicing signals
but there is no conserved internal splice signal.
However, with the accumulation of plant genomic DNA
sequence data, it is now becoming possible to predict
with some accuracy where intron splicing will occur
(Hebsgaard, S.M., P.G. Korning, N. Tolstrup, J.
Engelbrecht, P. Rouze and S. Brunak, Nucleic Acids
Research 24(17): 3439-3452, 1996). In fact, computer
programs that predict splice sites have now been
developed (the "PlantNetGene" server for splice site
predictions: http://www.cbs.dtu.dk/NetPlantGene.html).
From these sources, it appears that plant introns are
typically identified as T rich sequences.

Another factor affecting expression of foreign
genes in plants is codon preference. It is now well

-28-

known that preference for certain codons exist among
different phyla, classes, families, genera and species.
Accordingly, by modifying a DNA sequence so that it uses
codons preferred in a particular organism, expression of
5   that sequence can be optimized.

Other factors affecting the expression of
foreign genes in plants include the presence of putative
polyadenylation signals, hairpin cleavage consensus
motifs, polymerase II termination sequences and the Shaw-
10   Kamen sequence pattern ATTTA.

This example describes the design and
construction of "pl-ole1", a modified *Saccharomyces
cerevisiae* OLE1 gene optimized for expression in
Arabidopsis and other plant species.

15   The nucleotide sequence of the *Saccharomyces
cerevisiae* OLE1 gene coding sequence has been described
in U.S. Patent No. 5,057,419 to Martin et al.
(incorporated by reference herein) and is set forth below
for convenience as SEQ ID NO:1 (open reading frame starts
20   at +11). The *S. cerevisiae* Δ-9 desaturase amino acid
sequence encoded by *OLE1* is set forth as SEQ ID NO:2.

I.   **Design of pl-ole1**

To modify *OLE1* for optimum expression in
plants, the *OLE1* sequence was first analyzed for cryptic
25   plant splice signals, using the PlantNetGene server for
splice site predictions. This analysis identified a
number of "high confidence" intron splice signals in the
OLE1 sequence. These are shown below (positions
correspond to position numbers in SEQ ID NO:1).

30   **Donor splice site, direct strand:**

5' - 3'   5' - 3'

Position   Strand   Confidence   exon^intron

(Start ATG = +1)

-29-

397	+	1.00	GCTCTCTCTG^GTAAAGTACC
1052	+	0.85	CTATTAAGTG^GTACCAATAC
1074	+	1.00	CCCAACTAAG^GTTATCATCT

Acceptor splice site, direct strand:

5' - 3' Position	Strand	Confidence	5' - 3' intron^exon
500	+	0.86	GGTCTCACAG^ATCTTACTCC

Next, the *OLE1* peptide sequence (SEQ ID NO:2) was back-translated using an *Arabidopsis thaliana* codon usage table, as shown below. Codon usage in *Arabidopsis* and several other plant species, including *Brassica napus*, *Phaseolus vulgaris* and *Zea mays* is very similar, as can be seen by a comparison with the respective codon usage tables of those species, also shown below (the codon usage table of *Saccharomyces cerevisiae* is shown for comparison; codon usage tables taken from Ahttp://biochem.otago.ac.nz:800/ Transterm/codons.html).

Arabidopsis thaliana.

5

For each amino acid, the new *pl-olel* gene was
designed the codon most preferred in *Arabidopsis*, with
the following exceptions:

10   1.   The codon for glutamine CAG was
switched to CAA.   Though the codon preference for
glutamine is the same for both CAG and CAA in
Arabidopsis, CAA was used since the AG motif is part of
the 3' intron splice signal.

15   2.   In *OLE1*, there are regions of high
leucine/valine amino acid usage (e.g., between positions
322 to 571 of the nucleotide sequence are codons coding
for 11 leucines and 7 valines).   These regions correspond
to the *OLE1* protein transmembrane domains.   If the most

20 preferred codons in *Arabidopsis* (CTT and GTT,
respectively) were used, the region would take on the
characteristics of a plant intron, i.e., high T content,
thereby introducing a number of highly probable 5' splice
sites, which could not be removed without altering the

25 amino acid sequence.   Accordingly, a mixture of
alternative codons was used for these amino acids.
Similar changes were also applied to two other regions of
OLE1 (positions 781 to 900 and positions 1081 to 1140).

Next, a search for problematic sequences, such

30 as putative polyadenylation signals, hairpin cleavage
consensus motifs, ATTTA motifs or concatamers thereof,
was conducted.   Such sequences are described in detail in
U.S. Patent No. 5,380,831 to Adang et al. (incorporated
by reference herein).   This search identified one hairpin

35 cleavage consensus motif, CTTCGG, at position 553-559 of

-39-

SEQ ID NO:1, which was removed by changing TTC to TTT
(both encoding phenylalanine).

   Next, a BamHI site and translation initiation
consensus were added to the 5' end of the *OLE1* coding
5   sequence (M. Kozak, J. Biol. Chem. <u>266(30)</u>: 19867-19870,
1991). An XbaI and a BamHI site were added to the 3' end
of the coding sequence. A PacI site was introduced into
the same position as the original *S. cerevisiae OLE1* PacI
site (within the cytochrome b_5 domain), in order to
10   provide a convenient restriction site for construction of
this and other synthetic *OLE1* genes. Other convenient
restriction sites, which enable modular construction of
synthetic *OLE1* genes, are inherent within the final
sequence of the new *pl-ole1* gene.

15   Finally, the termination codon was checked
against a stop codon consensus database, "TransTerm"
(Dalphin et al., Nucl. Acids Res. <u>25(1)</u>: 246-247, 1997).
The existing termination sequence, TGAT, appeared
suitable for use in *Arabidopsis*, and so was not altered.

20   **II.   Construction of *pl-ole1*:**

   The rebuilt *pl-ole1* nucleotide sequence was
constructed commercially (Operon Technologies, Inc.).
The plasmid containing the rebuilt gene was designated
pAMCM013. The *pl-ole1* nucleotide sequence is set forth
25   below as SEQ ID NO:3 (open reading frame starts at +11).
This sequence encodes SEQ ID NO:2, but differs from the
S. cerevisiae OLE1 gene (SEQ ID NO:1) in the following
respects (summarized from above):

   1.   *Arabidopsis thaliana* codon usage; CAG
30   switched to CAA for glutamine;

      2.   Translation initiation consensus added;

      3.   Hairpin removed;

      4.   Several (but not all) PlantNetGene

-40-

predicted splice sites removed;

        5.   Eleven leucines changed from CTT to CTC, and 7 valines changed from GTT to GTG in positions 322-571, which corresponds to a plant intron-like region; similar changes made in regions 781-900 and 1081-1140; valine at position 432 retained as GTT to maintain Psp1406I site;

        6.   Certain leucine and valine codons were altered so that the same codons would not appear adjacent to others;

        7.   Intron acceptor site at position 1047 altered;

        8.   Restriction sites added to allow modular construction; PsP1406I site removed at position 1441; and

        9.   PacI site introduced at position 1362; an introduced NgoMI site at position 867 removed.

        A gap alignment of SEQ ID NO: 1 (top) and SEQ ID NO: 3 (bottom) is shown below:

Gap alignment of wild type and rebuilt OLE1 sequences.
Percent Similarity: 79.871   Percent Identity: 79.871

The *pl-ole1* synthetic gene contains no intron-
like regions, or predicted splice sites within its
sequence. Moreover, comparing the codon usage of
Arabidopsis with that of *Brassica napus*, *Phaseolus*
vulgaris or *Zea mays*, with the exception of cystein (a
rare amino acid that comprises 1.7% of all *Arabidopsis*
codons, and occurs 4 times (0.8%) in *OLE1*), the sequence
contains no rare codons for any of those species. The
codon usage of *pl-ole1* is particularly similar to the
preferred usage of *Brassica napus*. Accordingly, *pl-ole1*
is expected to be particularly well expressed in all
those species, and well expressed in any plant species.

An alternative version of *pl-ole1*, referred to
herein as *pl-ole1-2*, was also constructed. This
synthetic gene was modified only in specific codons
identified as high frequency splicing signals. It was
discovered that this construct is expressed equally as
well as *pl-ole1* in *Arabidopsis*.

                          EXAMPLE 2
             Vacuum Infiltration Transformation of
             Arabidopsis thaliana with *pl-ole1*

A modification of a transformation protocol of
Pam Green (http://www.bch.msu.edu/pamgreen/vac.html) was
used for the transformation of *A. thaliana* with *pl-ole1*.

-44-

The protocol was adapted from protocols by Nicole
Bechtold and Andrew Bent. This protocol gives very good
results, with 95% of all infiltrated plants giving rise
to transformants, and a transformant in up to 1 in 25
5   seeds.

PROTOCOL:

1.   Seeds of *Arabidopsis thaliana* ecotype
Columbia were sown in lightweight plastic pots prepared
10   in the following way: mound *Arabidopsis* soil mixture into
3 to 4 inch pots, saturate soil with *Arabidopsis*
fertilizer, add more soil so that it is rounded about 0.5
above the edge.

2.   Plants were grown under conditions of 16
15   hours light / 8 hours dark at 20°C, fertilizing with
Arabidopsis fertilizer once a week from below, adding
about 0.5 L to each flat. After 4-6 weeks, plants were
considered ready for vacuum infiltration when primary
inflorescence was 10-15 cm tall and the secondary
20   inflorescences appeared at the rosette. The bolts were
clipped back and 2 to 3 days was allowed for them to
regrow before infiltration.

3.   In the meantime, the construct was
transformed into *Agrobacterium tumefaciens* strain
25   (LBA4404). When plants were ready to transform, a 50 mL
culture of LB medium containing 50 mg/L kanamycin and 50
mg/L of streptomycin was inoculated with a 1 mL overnight
starter culture.

4. Cultures were grown overnight at 28° C with
30   shaking. The culture was pelleted, the supernatant
removed, and the pellet resuspended in 250 ml of
infiltration medium to OD600 >0.8. Infiltration medium
(1 liter) comprised 2.2 g MS salts, 1 X B5 vitamins, 50 g

-45-

sucrose, 0.5 g MES, pH to 5.7 with KOH, 0.044 =B5M
benzylaminopurine, 200 =B5L Silwet L-77 (OSi
Specialties).

   5.   The resuspended culture was placed in a
magenta jar inside a large bell jar. Pots containing
plants to be infiltrated were inverted into the solution
so that the entire plant was covered, including rosette,
but none of the soil was submerged.

   6.   A vacuum of 400 mm Hg (about 17 inches) was
drawn. Once the vacuum level was reached, the suction was
closed and the plants allowed to remain under vacuum for
five minutes. The vacuum was then quickly released. The
pots were briefly drained, then placed on
their sides in a tray, which was covered with a humidome
to maintain humidity. The next day, the plants were
removed to the growth room, the pots uncovered and set
upright. Plants infiltrated with different constructs
were kept separated in different trays thereafter.

   7. Plants were allowed to grow under the same
conditions as before. Plants were staked individually as
the bolts grew. When plants were finished flowering,
water was gradually reduced, then eliminated to allow the
plants to dry out. Seeds were harvested from each plant
individually.

   8. Large selection plates were prepared: 4.3
g/L MS salts; 1 X B5 vitamins (optional); 1 % sucrose;
0.5 g/L MES pH to 5.7 with KOH; 0.8% phytagar -
Autoclaved, then added antibiotics (35 μg/mL kanamycin
and 250 μg/mL of carbenicillin) and 150 X 15 mm plates
were poured.

   9.   Plates were dried well in the sterile hood
before plating - 20-30 minutes with the lids open was
usually sufficient.

-46-

10. For each plant, up to 100 μL of seeds (approximately 2500 seeds) was sterilized and plated out individually. Seeds were sterilized as follows: 1 min in 70% ethanol, 7 minutes in 50% bleach / 0.02 % Triton X-100 with vortexing, 6 rinses in sterile distilled water. Seeds were resuspended in 2 mL sterile 0.1% agarose and poured onto large selection plates as if plating phage. Plates were tilted so seeds were evenly distributed, and allowed to sit 10-15 minutes, during which time the liquid soaked into the medium. Plates were sealed with Parafilm and placed in a growth room.

11. After 7 to 10 days, transformants were visible as dark green plants. These were transferred onto "hard selection" plates (100 x 15 mm plates with same recipe as selection plates but with 1.5 % phytagar) to eliminate any pseudo-resistants, then replaced in the growth room.

12. After 10 to 14 days, the plants possessed at least two sets of true leaves. At this point, plants were transferred to soil, covered with plastic, and moved to a growth chamber with normal conditions. They were typically kept covered for several days.

Solutions:

-47-

1000X B5 vitamins (10 mL):

        1000 mg myo-inositol

        100 mg thiamine-HCl

        10 mg nicotinic acid

5   10 mg pyridoxine-HCl

        Dissolve in ddH2O and store at -20 °C.

Arabidopsis fertilizer (10 liters):

        50 mL 1M KNO3

10   25 mL 1M KPO4 (pH 5.5)

        20 mL 1M MgSO4

        20 mL 1M Ca(NO3)2

        5 mL 0.1M Fe.EDTA

        10 mL micronutrients (see below)

15   Dissolve in ddH2O and store at room temperature

Arabidopsis micronutrients (500 mL):

        70 mL 0.5M boric acid

        14 mL 0.5M MnCl2

20   2.5 mL 1M CuSO4

        1 mL 0.5M ZnSO4

        1 mL 0.1M NaMoO4

        1 mL 5M NaCl

        0.05 mL 0.1M CuCl2

25   Dissolve in ddH2O and store at room temperature

EXAMPLE 3
Customizing *OLE1* to Express
Post-Translational Modifications

30   After determining the optimized codon
preferences of *OLE1* mRNA (or mRNA derived from another
fungal or animal desaturase) for high level expression in
the host plant, specific amino acids that are involved in

-48-

the post-translational control of enzyme activity or
stability are altered to maximize the catalytic activity
of the expressed enzyme. There are a number of protein
kinase and/or phosphorylase consensus sequences that are
5   highly conserved in the fungal and animal desaturases.
These are shown below. First is shown a table of aligned
potential phosphorylation sites in desaturases. Next is
shown a pileup of Δ-9 fatty acid desaturases. PROSITE
analysis of these desaturases predicts a number of
10   potential phosphorylation sites, highlighted by bold
underlined characters.

Table 2 - Aligned Potential phosphorylation sites in desaturases. Phosphorylation sites are indicated with respect to amino acid positions in the Ole1p protein coding sequence. Abbreviations, S = serine, T= Threonine, A=Alanine, PKC - protein kinase C like; CK-2 - casein kinase II like; CAMP - cAMP activated kinase (PKA) like; np., not predicted as a phosphorylation site.

Residue position	Ole1p Residue	Ole1p sequence	Phosphory-lation type	Fungal/b5	Animal	Insect

Protein kinase (specifically cAMP- and

cGMP-dependent) phosphorylation sites.   There have been a

number of studies relative to the specificity of cAMP- and

cGMP-dependent protein kinases (Fremisco J.R. et al., J.

5   Biol. Chem. 255:4240-4245, 1980; Glass D.B., Smith S.B., J.

Biol. Chem. 258:14797-14803, 1983; Glass D.B. et al., J.

Biol. Chem. 261:2987-2993, 1986). Both types of kinases

appear to share a preference for the phosphorylation of

serine or threonine residues found close to at least two

10   consecutive N-terminal basic residues. It is important to

note that there are quite a number of exceptions to this

rule. However, the consensus pattern is as follows:

[RK](2)-x-[ST], where S or T is the phosphorylation site.

Protein kinase C phosphorylation site.   *In vivo,*

15   protein kinase C exhibits a preference for the

phosphorylation of serine or threonine residues found close

to a C-terminal basic residue (Woodget J.R. et al., Eur. J.

Biochem. 161:177-184, 1986;. Kishimoto A. et al., J. Biol.

Chem. 260:12492-12499, 1985). The presence of additional

20   basic residues at the N- or C-terminus of the

target amino acid enhances the Vmax and Km of the

-54-

phosphorylation reaction. The consensus pattern is: [ST]-x-[RK] where S or T is the phosphorylation site.

Casein kinase II phosphorylation site. Casein kinase II (CK-2) is a protein serine/threonine kinase whose activity is independent of cyclic nucleotides and calcium. CK-2 phosphorylates many different proteins. The substrate specificity (Pinna L.A., Biochim. Biophys. Acta 1054:267-284, 1990) of this enzyme can be summarized as follows: (1) Under comparable conditions Ser is favored over Thr; (2) an acidic residue (either Asp or Glu) must be present three residues from the C-terminal end of the phosphate acceptor site; (3) additional acidic residues in positions +1, +2, +4, and +5 increase the phosphorylation rate (most physiological substrates have at least one acidic residue in these positions); (4) Asp is preferred to Glu as the provider of acidic determinants; and (5) a basic residue at the N-terminus of the acceptor site decreases the phosphorylation rate, while an acidic one will increase it. The consensus pattern is: [ST]-x(2)-[DE] where S or T is the phosphorylation site (note: this pattern is found in most of the known physiological substrates).

If phosphorylation of a specific site by any kinase is found to increase the catalytic activity or stability of the encoded desaturase protein, the phosphorylated serine or threonine residue is changed to encode a negatively charged amino acid (aspartic acid or glutamic acid) in order to permanently optimize the activity or the protein. If phosphorylation of a specific residue is found to decrease the activity or stability of the encoded desaturase, the affected serine or threonine encoding codon is altered to substitute a neutral or a positively charged amino acid that will permanently optimize the activity or stability of the protein.

-55-

EXAMPLE 4
Further Modifications and Improvements of the *Saccharomyces cerevisiae* OLE1 Gene for Plant Expression Using Elements Derived from Native Plant Desaturase Genes

The activity of the native or modified forms of the *Saccharomyces cerevisiae* OLE1 Δ-9 desaturase gene in plant tissues may be further improved by the substitution or inclusion of elements derived from native plant desaturase genes. Favorable plant gene elements may include sequences that improve the expression of the modified gene at one or more levels, including the following: 1) transcription, 2) pre-mRNA processing, 3) mRNA transport from the nucleus to the cytoplasm, 4) mRNA stability 5) translation, 6) targeting or retention of the protein at the appropriate membrane surface or organelle surface, 7) protein folding and maturation, and 8) stability of the functional desaturase protein.

The inventors have shown that the *OLE1* gene can tolerate significant modifications without losing its biological activity. These modifications include deletion of the "coiled coil" region, the addition of 239 amino acids to the N-terminus of *OLE1p* and truncation of 55 and 60 amino acids from the N-terminal end of the protein. The inventors have also shown that modifications of the 5' and 3'untranslated regions of the *OLE1* mRNA can significantly affect its stability. For example, removing a short open reading frame near the 5' "cap" region of the *OLE1* mRNA increases its half-life in *Saccharomyces* from 12 minutes to approximately 25 minutes. The existence of elements in the mRNA that affect its stability indicate that other elements might also exist that affect the stability of an mRNA generated by a synthetic gene in another host organism.

Plant desaturase gene elements that enhance the

-56-

function of the modified Δ-9 desaturase gene are identified
by a 2-step method. STEP 1 involves isolating a series of
DNA sequences from a cDNA that encodes a plant ER lipid
biosynthetic enzyme. Those elements are linked, or
5   inserted into regions of a native or "optimized" gene under
control of a yeast promoter in a vector suitable for
expression in *Saccharomyces cerevisiae*. The resulting
vectors are then tested for their ability to produce
functional desaturase enzymes in strains of *Saccharomyces*
10   that contain an inactive form of the Δ-9 fatty acid
desaturase gene.

In STEP 2, plant desaturase sequences from the
above vectors that are found to produce a functional Δ-9
desaturase gene are used to a isolate homologous sequences
15   from plant genomic DNA. The isolated genomic sequences are
used to construct a synthetic gene that produces an mRNA
that encodes the same functional desaturase protein
produced by the vector in step 1. In this instance, the
genomic sequences encompass the same protein coding
20   elements as those encoded by the homologous cDNA sequence
and also include genomic elements that encode the 5' and/
or 3' untranslated regions of the plant desaturase mRNA.
These combined genomic elements should differ from the cDNA
derived sequences used in STEP 1 by containing authentic
25   plant introns, (which may facilitate efficient and correct
splicing of the chimeric mRNA in the plant nucleus) and
signals that affect the mRNA stability, mRNA transport, and
efficient translation of the mRNA in plant tissues. The
chimeric plant / synthetic gene containing the genomic
30   sequences is inserted into vectors under the control of
plant seed-specific promoters and tested for expression and
desaturase function in plants, including *Brassica,*
Arabidopsis, maize and soybeans.

-57-

The following specific examples further illustrate these methods employing the *Arabidopsis FAD2* gene, which encodes an ER Δ12-desaturase, as a source of plant desaturase DNA sequences. In the preferred

5 embodiment, the source of the plant desaturase DNA would be the *FAD2* homolog, or a related ER lipid biosynthetic gene, that is derived from the same plant species that is intended to be modified by the resulting vector for commercial use.

10

A.   Substitution of the N-terminal *OLE1* protein coding sequences and with N-terminal sequences from the derived from the Arabidopsis FAD2 gene.

1) A cDNA containing the FAD2, Δ-12 desaturase,

15 mRNA coding sequence is isolated by reverse transcriptase - polymerase chain reaction (RT-PCR) of isolated mRNAs derived from Arabidopsis tissue or by direct DNA synthesis using the protein and DNA sequences set forth in SEQ ID NO:4 and SEQ ID NO:5 (open reading frame starts at +93).

20 2) The inventors have shown that substitution of transmembrane sequences of the *OLE1* gene with transmembrane sequences from the *Saccharomyces FAH2* gene abolishes Δ-9 desaturase activity. *FAH2* encodes a sphingolipid fatty acid hydroxylase, which is an ER membrane protein.

25 TMPredict analysis of the *Arabidopsis FAD2* sequence indicates that the first transmembrane region of its encoded protein begins at residue +52 and a similar analysis of the *OLE1* sequence indicates that its first transmembrane sequence begins at residue +113. Because the

30 inclusion of potential membrane spanning elements from the plant desaturase could produce significant changes in the desaturase core enzyme structure that affect activity, only sequences encoding residues +1 to +52 of FAD2 are tested

-58-

for functional linkages or substitutions in the 113 residue
N-terminal region of *OLE1*.

        A series of PCR oligonucleotide primers are
synthesized that include a 5' primer that complements
5   sequences including +1 start codon of the *FAD2* gene and 3'
primers that complement sequences ending, for example, at
residues +20, +35 and + 52 of the *FAD2* gene. These are
used to amplify a series of fragments of different lengths
from the *FAD2* cDNA that extend from the +1 codon through
10   codon +52. A second PCR amplification is performed using a
5' primer that is complementary to sequences that include
the 5' end of the *FAD2* mRNA and the 3' primer that includes
codon +52. That amplification is done using *Arabidopsis
genomic* DNA as a template. The amplified fragment from
15   that reaction is cloned into a bacterial vector and
subjected to DNA sequencing to detect the presence of
introns within the genomic sequence. The cloned genomic
fragment is also used to construct vectors for plant
expression as indicated in STEP 2 of the method.

20   The amplified cDNA fragments is inserted into
yeast expression vectors that contain the native *OLE1* mRNA
coding sequence under the control of the *Saccharomyces*
galactose inducible, *GAL1* promoter. Insertion of the plant
DNA fragments can be done in several ways: 1) A fragment is
25   inserted upstream of the *OLE1* protein coding sequences so
that its protein coding element is fused in frame to the +1
codon of the *OLE1* encoded protein, 2) the codons on the
plant fragment could replace the equivalent *OLE1* residues
starting from the +1 ATG codon (e.g. a plant DNA fragment
30   containing codons +1 -> +52 replaces *OLE1* codons +1 ->
+52) and 3) the full length fragment containing codons +1 -
> + 52 of the plant gene is fused in frame to codon +114 of
the *OLE1* gene, replacing the *OLE1* residues +1 -> +113 with

-59-

plant desaturase residues +1 ->   +52.

      The resulting plasmids are transformed into a haploid *ole1Δ::LEU2* strain of *Saccharomyces*. That strain contains a null, disrupted form of the *OLE1* gene and

5   therefore has a growth requirement for unsaturated fatty acids. The transformed *Saccharomyces* strains are grown on fatty acid depleted galactose medium to test for the ability of the induced chimeric gene to support growth of the strain without fatty acids. Transformed strains that

10   grow on the fatty acid deficient medium are further analyzed to assess the effects of the plant sequences on desaturase function. This is done by Western blot analysis, to measure levels of the resulting desaturase protein and by fatty acid analysis of total cellular

15   lipids, to assess the relative activity of the desaturase enzyme by comparison of the ratio of saturated to unsaturated fatty acids.

      3) Using information derived from the above tests, a chimeric desaturase gene is constructed using the

20   amplified genomic DNA from the *FAD2* gene. Construction, testing, and analysis these vectors is guided by the principle that the most desirable vector is one that maximizes the use of the plant gene sequences and minimizes the use of the *Saccharomyces* Δ-9 desaturase gene sequences

25   while retaining optimal desaturase function. Plant DNA fragments derived from the genomic DNA amplification that extend from the 5' end of the mRNA sequence to the longest sequence that produces optimal desaturase function in yeast are inserted into a vector containing the native Δ-9

30   desaturase gene (or one of its modified forms produced by the methods described above). The fragment is inserted into the vector so that the 3' end of its protein coding sequence produces an mRNA that generates a protein sequence

-60-

identical to its counterpart derived from the *FAD2* cDNA
sequences. The resulting chimeric desaturase gene, which
now encodes an mRNA that includes the FAD2 5' untranslated
region in addition to the modified protein coding

5   sequences, is placed into a plant expression vector under
the control of a suitable plant promoter and plant
termination/ polyadenylation sequences.

4) The resulting vectors containing the
plant/yeast chimeric desaturase sequences are transformed

10   into plants for testing and analysis of desaturase
function. Suitable test plants include *Arabidopsis*
thaliana, and *Brassica napis*. A method for transformation
and analysis of desaturase gene expression in *Arabidopsis*
is provided above. A method for transformation and

15   analysis of yeast desaturase expression in *Brassica napis*
is described in U.S. Patent No. 5,777,201 to Poutre et al.
(incorporated by reference herein).

B.   Insertion or substitution of Arabidopsis *FAD2*

20   **C-terminal protein coding sequences and 3' mRNA**
untranslated region sequences into native and modified
forms of the *OLE1* gene.

The inventors have previously shown that proteins
encoded by the *Saccharomyces ELO2* and *ELO3* genes contain a

25   series of charged residues in their C-terminal region.
These proteins are located on the ER surface and function
in the biosynthesis of very long chain fatty acids as
described in Oh et al. (J. Biol. Chem. 272: 17376-
17384, 1997) (incorporated by reference herein). They

30   further showed that deletion of the region containing the
charged residues causes the proteins to be mislocalized
from their normal cellular locations in the endoplasmic
reticulum, resulting in reduced function. Similar clusters

of charged residues occurs in the C-terminal region of the
OLE1 gene that are apparently associated with ER retention
or localization. These residues do not appear to be a part
of the functional cytochrome b$_5$ domain. A detailed

5   comparison of the C-terminal *OLE1* and the Arabidopsis FAD2
sequences show that the plant desaturase has similar, but
not identical, clusters of charged residues to those in the
OLE1 gene. These sequences are shown below:

10   **SEQ ID Nos: 6 and 7**:

Comparison of the charged carboxyl terminal amino acids of
Ole1p (SEQ ID NO:7) and the Arabidopsis Fad2p desaturase
(SEQ ID NO:6) (The region of the *OLE1* gene shown does not
appear to be a functional part of its cytochrome b$_5$

15   domain) .

Methods similar to those shown in Section A can be used to

25   identify *Arabidopsis* FAD2 sequences that can replace the
OLE1 C-terminal sequences to optimize gene expression,
membrane targeting and ER retention of the chimeric enzyme.
1) A series of oligonucleotide primers for PCR
amplification are synthesized for isolation of elements in

30   the C-terminal region of the *FAD2* gene. A *FAD2* DNA
fragment encompassing that region is generated by PCR
amplification of the cDNA clone. Alternatively, given the
smaller size of the fragment it or modified forms of the
plant fragment may be generated directly by DNA synthesis.

-62-

A fragment containing that region and its flanking 3'
untranslated region also is generated by PCR amplification
of *Arabidopsis* genomic DNA as described above. That
fragment is cloned into an appropriate vector and sequenced,
5   as also described.

          2) Vectors are constructed that contain the plant
DNA fragments linked to or substituted into the *OLE1* C-
terminal coding region as described in Section A. In this
instance, the plant DNA fragments are linked in frame to
10   the carboxyl terminal residues of the *OLE1* protein coding
region.

          3) The resulting vectors are transformed into the
Saccharomyces *ole1Δ* strain and tested for desaturase
function as described in Section A.

15   4) Using information derived from the above
tests, chimeric desaturase genes containing the C-terminal
plant sequences that produce functional desaturases are
constructed using the amplified genomic DNA from the FAD2
gene, according to the principles outlined in Section A.
20   The resulting sequences are employed to construct vectors
that will express the chimeric plant/yeast gene under
control of plant promoter and plant termination/
polyadenylation sequences. Those vectors are transformed
into plants for testing and analysis of desaturase function
25   as described above.

          The present invention is not limited to the
embodiments described and exemplified above, but is capable
of variation and modification without departure from the
30   scope of the appended claims.
